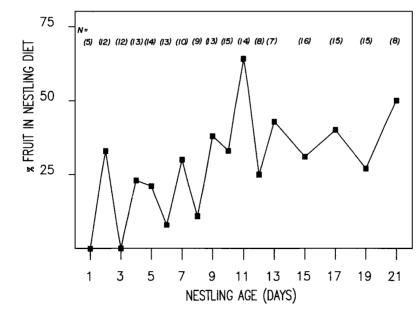

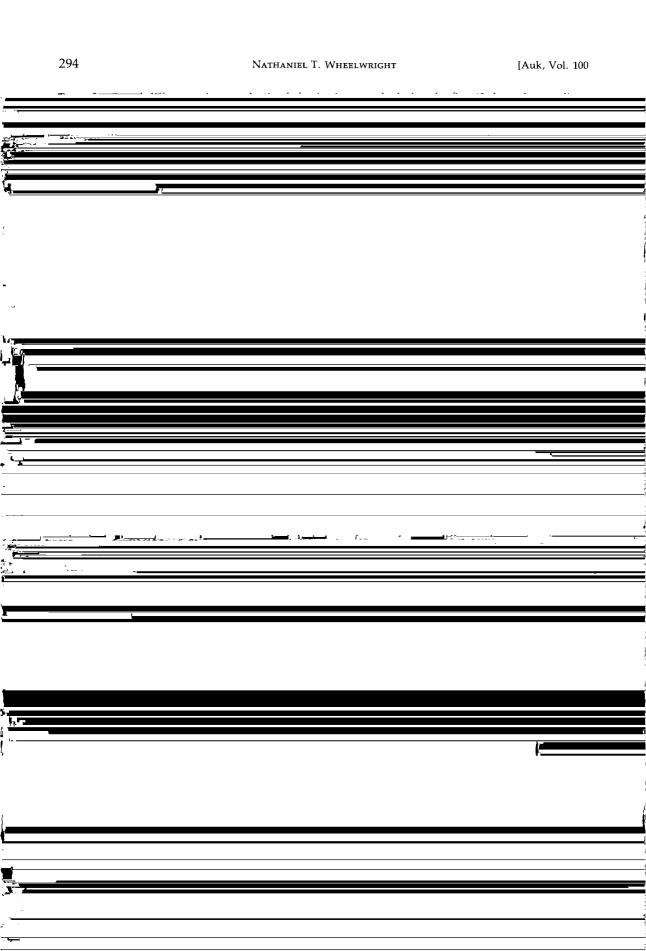

Fig. 2. Age versus proportion of fruit in the diet of nestling quetzals at nest 1. Spearman Rank Correlation: $r_s = 0.62$; P < 0.01. The number of food items for which frequencies were calculated is listed above each point. Each point represents 4–5 h of observation (71 h in total).

most entirely animal food" (insects, snails, lizards, and frogs) until the 10th day; fruits became important in the diet only after the 14th day. In the Monteverde population, certain in-

insects, in particular beetles and grasshoppers, than did the female (Table 2; χ^2 One-sample Test: P < 0.01). The male also made significantly more deliveries in total (P < 0.01; χ^2 One-

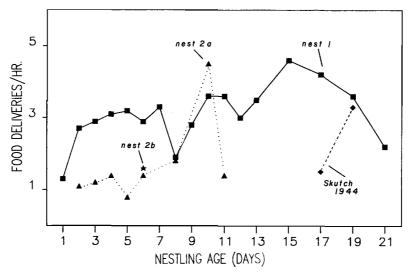

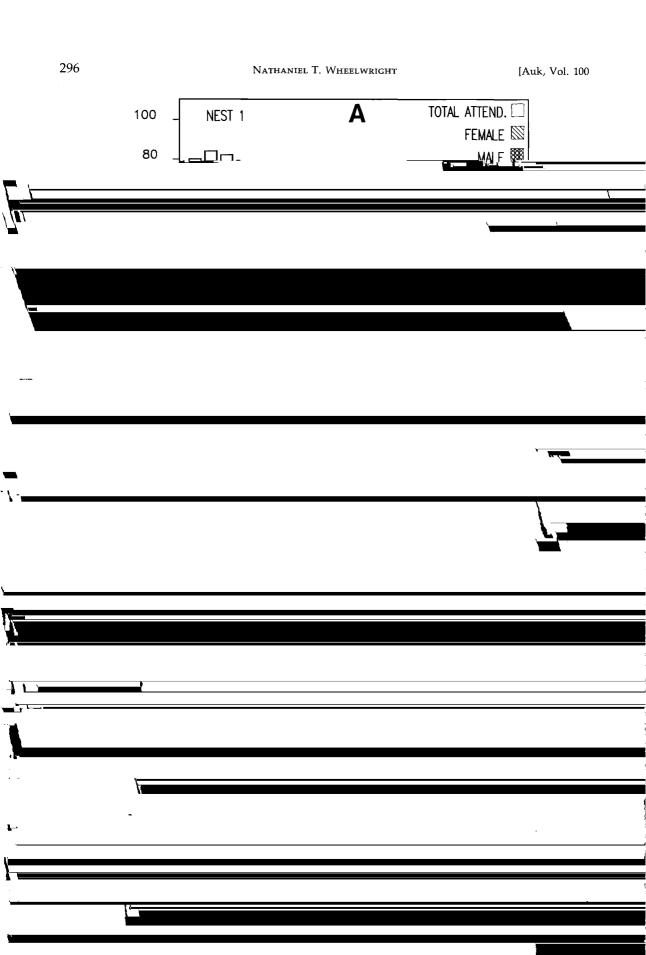

Fig. 3. Nestling age versus hourly rate of food delivery in quetzals. \blacksquare = nest 1 (two nestlings until day 20; first clutch): \blacktriangle = nest 2 (one nestling: second clutch): \blacktriangle = data

from Skutch (1944).

of light gaps or pastures, and 14% in snags in the open. Of 40 nests, 11 faced north-northeast, 13 east-southeast, 7 south-southwest, and 9 west-northwest. Nests were excavated in decaying *Ocotea tonduzii* and other Lauraceae (8 of the 10 decomposing snags that could be identified), *Eugenia* sp. (1/10), and *Quararibea* sp. (Bombacaceae; 1/10). If the same snag was

and afternoon shifts, however, as Skutch (1944) did. In 16 observations at four nests, each sex incubated with equal frequency betwen 0800 and 1200; the female tended to be present during early morning and late afternoon and the male during early afternoon. Although La-Bastille et al. (1972) seldom noticed eggs uncovered for more than 2–13 min, I often found

ed 60–90° % of all seeds dropped by quetzals fall directly beneath the parent tree or within 100 m. Widely foraging tanagers or flycatchers probably spread seeds more effectively. Quetzals provide one aspect of high-quality seed dispersal, however, of which few bird species are capable, namely transporting bulky seeds (as in many Lauraceae) with substantial seedling reserves (McKey 1975).

birds, but at the moment we lack the data to

determine which differences are merely quan-

regularity in the availability of any one fruit species, birds are unlikely to evolve a strong interdependence with one or a few species (Howe 1981, Wheelwright and Orians 1982, Thompson 1982).

Crome's (1975) detailed study of fruit-pigeons in tropical Queensland suggests coevolution with, or at least dependence upon, fruiting plants at the family level, as in quetzals.

geon population movements mirrored the

changing abundance of lauraceous fruits. In the

birds for which fruit plays a less important role in their life histories. They also differ in many respects from other specialized fruit-eating.

Lauraceae are ripe, and 88% of the diet of one species consisted of fruits of the Lauraceae and Araliaceae alone_As_with quetzals_fruit-ni-

prey" (Snow 1971). Until now, the evidence for this postulate has come from analyses of time budgets of fruit-eating birds, which demonstrated that several species may spend only 8-17% of the during that during the Taylor of the deleterious effects of inbreeding (Soulé and Wilcox 1980).
